

Package ‘eqtl’

February 19, 2015

Type Package

Title Tools for analyzing eQTL experiments: A complementary to Karl Broman's 'qtl' package for genome-wide analysis

Version 1.1-7

Date 2012-3-6

Author Ahmid A. Khalili and Olivier Loudet

Maintainer Ahmid A. Khalili <ahmid.khalili@gmail.com>

Contributors Jennifer Yansouni, Karl Broman

Depends R (>= 2.10), qtl (>= 1.7.12)

Description Analysis of experimental crosses to identify genes (called quantitative trait loci, QTLs) contributing to variation in quantitative traits.

A brief introduction *Introductory comments on R/eqtl*

Description

A brief introduction to the R/eqtl package, with a walk-through of a typical analysis.

Preliminaries to R/eqtl

- In order to use the R/eqtl package, you must type (within R) `library(eqtl)`. This function will automatically load the R/qtl library required. You may want to include this in a `.Rprofile` file.
- Documentation and several tutorials are available from the R archive : <http://cran.r-project.org>.
- Use the `help.start` function to start the html version of the R help.
- Type `library(help=qtl)` to get a list of the functions in R/qtl.
- Type `library(help=eqtl)` to get a list of the functions in R/eqtl.
- Download the latest version of R/qtl and R/eqtl.

Walk-through of an analysis with R/eqtl

Here I briefly describe how to use R/eqtl to analyze an experimental cross. R/eqtl contains functions which required Karl Broman's R/qtl functions. This tutorial takes in consideration prior knowledge of R/qtl. Therefore, it is highly recommended that you read the R/qtl documentation and tutorials before you perform any analysis.

The data:

A difficult first step in the use of most data-analysis software is to import the data in an adequate format. This step is perfectly described in R/qtl tutorials. With R/eqtl you should import some extra data in addition to the data needed for R/qtl. We will not discuss data import at this point. This step is described in the chapter "Importing the data".

We consider the example data `seed10`, an experiment on gene expression in *Arabidopsis-thaliana*. Use the `data` function to load the data.

```
data(seed10);
```

seed10 data is formatted by read.cross function. This data object has class cross and riself and describes an experiment on an *A.~thaliana* RIL population. The function summary.cross gives summary information on the data, and checks the data for internal consistency. A lot of utility functions are available in R/qtl and are widely described in Karl's tutorials. Please note~: seed10 is too large to be viewed in the R window. What is shown is the average phenotypes. Is it possible to use the attributes function later to get a closer look.

To project our results on the physical map, we also need to load the physical position of the genetic markers and the genomic physical coordinates of the probes used to estimate expression traits described in seed10. For information, BSpmap and ATH.coord are simple data frames with specific column names.

```
data(BSpmap);
names(BSpmap);
data(ATH.coord);
names(ATH.coord);
```

The Interval Mapping:

Before running the QTL analysis, intermediate calculations need to be performed. The function calc.genoprob is used to compute the conditional probabilities at each pseudo-marker while sim.geno simulates sequences of genotypes from their joint probabilities. See R/qtl manual for details. These steps have already been performed on seed10 and you do not need to run them again. Here, pseudo-markers have been defined every 0.5 centimorgan by defining the parameter step=0.5 as described in the following lines.

```
#DO NOT RUN
seed10 <- calc.genoprob(seed10, step=0.5, off.end=0, error.prob=0,
map.function='kosambi', stepwidth='fixed');
#DO NOT RUN
seed10 <- sim.geno(seed10, step=0.5, off.end=0, error.prob=0,
map.function='kosambi', stepwidth='fixed');
```

The microarray probes usually contain data for which we don't want to perform any QTL analysis like the buffers, the controls or some missed probes. The function cleanphe cleans the seed10 data for undesired phenotypes.

```
seed10.clean <- cleanphe(seed10,"Buffer");
seed10.clean <- cleanphe(seed10,"Ctrl");
```

In this example, dropped data comes from probes named "Buffer" and "Ctrl" found within CATMA data. This function is based on the grep function of R. Thus it can be used to remove all the data defined within a specific word (for example "CHLORO" will remove all items that contain "CHLORO" within it).

Note that the function cleanphe can also be run on scanone object. This is useful in case of you forget to clean your cross object before running scanone. For this, you have to be very careful to what you're doing. It is indeed important for the next steps of the analysis to keep a cross object whose phenotypes fit perfectly with those described in scanone object.

Use the scanone function to perform an interval mapping.

```
BaySha.em <- scanone(seed10.clean,method='em',
                    pheno.col=1:nphe(seed10.clean),model='normal')
```

Keep in mind that `BaySha.em` is obtained from `seed10.clean` which has been removed of some phenotypes from `seed10`. Thus, the dataframe from now on corresponding to `BaySha.em` is always `seed10.clean`.

Mapping the QTLs:

Here start the main differences with `R/qtl`. One of the major problematic steps for genome-wide expression QTL analysis, is to read all the LOD curves and systematically define the QTLs. Because of the amount of results, it is not feasible to read the LOD curves by hand. `R/eqtl` allows to detect several QTL by chromosome with drop LOD support interval and a genetic exclusionary window.

Use `define.peak` function to define QTL with drop LOD support interval from the scanone results, here the interval mapping results `BaySha.em`.

```
BaySha.peak <- define.peak(BaySha.em, lodcolumn='all');
class(BaySha.peak);
```

The parameter `lodcolumn='all'` specifies to analyze all LOD columns (all the traits) of the scanone object `BaySha.em`. By using `lodcolumn='CATrck'`, it specifies to analyze only the the scanone LOD column `CATrck`, which is supposed to be the interval mapping result of the trait `CATrck`.

We call peak object, the results of the `define.peak` function. The peak object is used to store the QTL definition. The QTL are defined by several features described in the peak objects attributes. At this step, a QTL is only defined by its LOD score, location and the subjective quality of the LOD peak. See `define.peak` function for details.

```
attributes(BaySha.peak);
```

Within the `BaySha.peak` attributes, you can see the "scanone" that it record from which the scanone object the QTL was defined.

Back to the `define.peak` parameters. `graph=TRUE` specifies to draw the LOD curves with LOD support interval. The curves showing a QTL detected will be drawn on different charts for each chromosome. Note that, no graphical setup has been defined and therefore all graphs generated will appear one above the others. You should specify the graphical parameter `mfrow` of the `R` function `par()` before running `define.peak` to draw all charts in the same window. You may not want to set the parameters `graph=TRUE` and `lodcolumn='all'` at the same time, depending on the amount of traits analyzed.

The following command lines is an example to define QTL and draw chart for a unique trait `CATrck`. Because *A.~thaliana* genome contains 5 chromosomes, 5 charts will be drawn for a unique trait.

```
png(filename='CATrck.png',width=800,height=600);
par(mfrow=c(1,5));
define.peak(BaySha.em, lodcolumn='CATrck', graph=TRUE, chr=c(1,5));
par(mfrow=c(1,1));
dev.off();
```

`png()` and `dev.off()` are classical `R` functions which indicates here to print the graph generated as a png file '`CATrck.png`'. By using these functions, you can page set the graph as you would like it. By adding `save.pict=TRUE`, to `define.peak` function parameters, will systematically save all single LOD curves generated for each chromosome as png files. The files generated will

be named with the names of the trait and the chromosomes where the QTLs are located. Pay attention to the amount of data you're analysing before setting the parameters `save.pict=TRUE`. The way to access QTL results within peak object is quite simple:

```
BaySha.peak
BaySha.peak$CATrck
```

`BaySha.peak` will give you the `define.peak` results ordered by trait and chromosomes, respectively. `BaySha.peak$CATrck` will give you the results for the trait 'CATrck' and so on for other trait names. If no QTL had been detected for a trait, the result will be the value NA. To avoid to save all charts, I first run `define.peak` for all traits (`lodcolumn='all'`) and save the results as a peak object. Then, when I need to check how look like the LOD curve of a specific trait, I run `define.peak` again on this trait by setting `graph=TRUE` without saving the peak object obtained.

Defining the QTLs:

To complete the QTL analysis, use the functions `calc.adeq`, `localize.qtl` and `classify.qtl` to compute, for each QTL previously detected in peak object, the additive effect, the estimated physical location and the estimated acting-type in case of eQTL, respectively. All of these functions will add peak features to the peak object.

```
BaySha.peak <- localize.qtl(cross=seed10.clean, peak=BaySha.peak,
data.gmap=BSpgmap);
BaySha.peak <- calc.adeq(cross=seed10.clean, scanone=BaySha.em,
peak=BaySha.peak);
BaySha.peak <- classify.qtl(cross=seed10.clean, peak=BaySha.peak,
etrait.coord=ATH.coord, data.gmap=BSpgmap);
attributes(BaySha.peak);
```

For each of these functions you have to specify the peak object. You also need to specify the related cross object and scanone results, the related genetic map physical data `BSpgmap` and the expression traits physical data `ATH.coord`. Note that, the expression trait physical data (here `ATH.coord`) may contain more traits than those studied. Conversely, all traits studied within the peak, the scanone or the cross objects must be described in `ATH.coord`. As you can see, the name of the cross object has been recorded in the attributes of the `BaySha.peak` object

Use `calc.Rsq` function to compute, from the peak object, the contribution of the individual QTLs to the phenotypic variation. At the same time this function tests and computes the contribution of significant epistatic interactions between QTLs. By default the significant threshold is set to `th=0.001`. In case you wanted to take all QTL interactions whatever the significance, you must set `th=1`.

```
BaySha.Rsq <- calc.Rsq(cross=seed10.clean, peak=BaySha.peak);
BaySha.Rsq;
plotRsq(rsq=BaySha.Rsq);
```

Manipulating the results:

The function `peak.2.array` will format all QTL results in a simple array. The column names are the names of the peak features described in peak object. This array has the class `peak.array`. `Rsq.2.array` adds the R square column to the QTL array. Formatting the results as a simple array allows the use of all basic and complex R functions (statistical, summary, graphical, histograms...) which will allow us to customize the data in the simplest way. This format also allows to write the results in a file (like text or CSV) to save out the data.

```
BaySha.array <- peak.2.array(BaySha.peak);
BaySha.array <- Rsq.2.array(rsq=BaySha.Rsq,BaySha.array);
```

R/eqt1 provides useful functions that give an overview of the QTLs results stored in `peak.array`. The `peaksummary` function gives a variety of summary information and an overview of peak distribution. Summary graphs are available by setting `graph=TRUE`. Like `define.peak`, no graphical parameters had been set and therefore all graphs generated will appear one above the others in the same R graph window. You may define `mfrow` before running `peaksummary` to draw all charts in the same R window.

Whole QTL summary with graphs:

```
par(mfrow=c(3,4));
BaySha.summary <- peaksummary(BaySha.array,seed10.cleaned,graph=TRUE);
par(mfrow=c(1,1));
names(BaySha.summary);
BaySha.summary;
```

QTL summary with graphs excluding QTL localized on the chromosome 3 between 5000 and 6000 bp:

```
par(mfrow=c(3,4));
BaySha.sum_exc <- peaksummary( BaySha.array, seed10.cleaned,
exc=data.frame(inf=5000, sup=6000, chr=3), graph=TRUE);
par(mfrow=c(1,1));
names(BaySha.sum_exc);
BaySha.sum_exc;
```

The function `genoplot` provides basic information and an overview about genome-wide eQTL parameters.

```
genoplot(BaySha.array,seed10.clean, ATH.coord, BSpgmap,
chr.size=c(30432457, 19704536, 23470536, 18584924, 26991304),
save.pict=TRUE);
```

The parameter `chr.size` is the size of the chromosomes in base pair (here *A. thaliana*). These sizes are used to delimit the chromosomes for genome-wide graphs. For this function, the page setting has already been specified, `save.pict=TRUE` will save all graphs in different files within the current folder.

The Composite Interval Mapping:

Use the function `cim.peak` to systematically perform composite interval mapping by running a single genome scan `scanone` with previously defined QTL as additive covariates. The additive covariates are defined from the peak object as the closest flanking marker of LOD peaks with the function `map.peak`. The `cim.peak` function returns an object of the `scanone` class and therefore can be analyzed by the `define.peak` function. The results can then be analyzed by `calc.adeq`, `localize.qtl`, `calc.Rsq`, etc... Due to the model, the LOD curves present a high (artefactual) LOD peak at the additive covariates locations which will be incorrectly detected as a strong QTL by the `define.peak` function. To avoid this, use the `wash.covar` function which will set the LOD score at the covariates location to 0 LOD. This function takes care of a genetic window size which specifies the size of the region to “wash”.

```

BaySha.cem <- cim.peak(seed10.clean,BaySha.peak);
covar <- map.peak(BaySha.peak) ;
covar;
BaySha.cem <- wash.covar(BaySha.cem, covar, window.size=20);
BaySha.cem.peak <- define.peak(BaySha.cem, lodcolumn='all');
BaySha.cem.peak <- calc.adeff(cross=seed10.clean, scanone=BaySha.cem,
peak=BaySha.cem.peak);
BaySha.cem.peak <- localize.qtl(cross=seed10.clean, peak=BaySha.cem.peak,
data.gmap=BSpgmap);
BaySha.cem.peak <- classify.qtl(cross=seed10.clean, peak=BaySha.cem.peak,
etrait.coord=ATH.coord, data.gmap=BSpgmap);
BaySha.cem.Rsq <- calc.Rsq(cross=seed10.clean, peak=BaySha.cem.peak);
plot.Rsq(BaySha.cem.Rsq);
BaySha.cem.array <- peak.2.array(BaySha.cem.peak);
BaySha.cem.array <- Rsq.2.array(BaySha.cem.Rsq,BaySha.cem.array);

```

You now have two `peak.array`. `BaySha.array` which contained the results from IM analysis and `BaySha.cem.array` which contained the results from CIM. You may want to merge these two `peak.array` in one to run the `genoplot` function using all QTLs from IM and CIM. Note that you may have to add manually the class `peak.array` to the merge array obtained.

```

BaySha.em.cem.array <- rbind(BaySha.em.array,BaySha.cem.array);
attributes(BaySha.em.cem.array)$class<-c("peak.array","data.frame");

```

ATH.coord

Data on probes coordinates

Description

Data for the physical coordinates of *A. thaliana* GST (probes).

Usage

```
data(ATH.coord)
```

Format

A data frame with 487 observations with the following 4 variables representing GST genomic coordinates:

etrait.name a factor with GST names as levels

chr an integer vector corresponding to the chromosomes.

start an integer vector corresponding to the GST start location in base pair.

stop an integer vector corresponding to the GST stop location in base pair.

Details

The CATMA microarray, composed of Gene Sequence Tag (GST) referenced below, correspond to the expression phenotypes measured on their related cross object (here, they describes the seed10 object). Usually, all expression traits are not taken into account within a QTL analysis, therefore this list could contain more traits than the ones phenotyped within the cross object. On the other hand, every phenotype analysed must be found within ATH.coord data frame. Please note that ATH.coord contains the physical locations values of an anonymized GST sample taken from true CATMA 2 data which originally contains 30334 GST. The complete data is available on from the TAIR or CATdb websites.

data(ATH.coord);
```

BSpgmap

Genetic map data of a RIL population

Description

Genetic map of physical data of an *Arabidopsis-thaliana* Recombinant Inbred Line population

Usage

```
data(BSpgmap)
```

Format

A data frame with 69 observations on the following 3 variables representing the physical location of genetic markers:

Marker a factor with genetic marker names as levels.

chr a numeric vector determining the chromosomes.

PP a numeric vector determining the markers physical position on the chromosome in base pair (bp).

Details

Physical data of the 33RV population genetic map. This population was created from a Bay0 x Sha cross by Olivier Loudet and Sylvain Chaillou between 1997 and 2000 at INRA Versailles. For complete description of the population see reference below.

```

calc.adeff

Compute the additive effect at each QTL marker

Description

Computes the additive effect at QTL marker by meaning the phenotypic value for each genotypic group.

Usage

```
calc.adeff(cross, scanone, peak, round, ...)
```

Arguments

cross	An object of class cross. See 'qtl' package manual for read.cross function details.
scanone	An object of class scanone. See 'qtl' package manual for read.cross function details.
peak	An object of class peak. See define.peak function for details.
round	An optional integer indicating the precision to be used for the additive effect value. See round function for details.
...	Additional arguments passed to the functions plot and effectplot when it is called.

Details

Uses Karl Broman's `effectplot` function to mean the phenotype for each genotypic group defined at the QTL marker. The additive effect is computed as the difference between the phenotypical means of the two genotypic groups (homozygous). The parental reference allele is allele 2. By default, allele 1 is encoded as A and allele 2 as B, therefore the additive effect is **mean(B)-mean(A)** where **mean(A)** is the phenotypical mean of genotypic group A and **mean(B)** is the phenotypical mean of the genotypic group B.

Value

The input peak object is returned with component, `adeff`, added to components of `peak` for each previously detected QTLs.

`additive.effect`

The additive effect value at the QTL marker

Note

It is necessary to have previously performed the `sim.geno` function. It is not recommended to plot the allelic contribution by using the function `calc.adeff`. It is preferable to use directly Karl Broman's `codeeffectplot` function (using the parameter `draw=TRUE`). See 'qtl' package manual for `codeeffectplot` function details.

```

calc.Rsq

Estimate R square of individual QTLs and QTL interactions

Description

Estimates the R square (phenotypic contribution) for individual QTLs and their significant interactions for each trait from cross and peak objects.

Usage

```
calc.Rsq(cross,peak,th=0.001,round)
```

Arguments

cross	An object of class cross. See 'qtl' package manual for read.cross function details.
peak	An object of class peak. See define.peak for details.
th	A numeric vector of length 1 with value between 0 and 1. The R square significance threshold to keep the R square values.
round	An optional integer indicating the precision to be used for the R square value and it significance. The function 'round' is used for R square value rsq. The function 'signif' is used for the significance pF (i.e. p(F)). See round and signif functions for details.

Details

Estimates the proportion of the phenotypic variation explained by the segregation of an individual QTL or significant QTL interactions (also called R square). Compute R square i.e. to compare the phenotypic variation explained by the presence of a genetic determinant (an individual QTL or a QTL's interaction) with the total phenotypic variation. Here we use an AnOVA with a linear model including all possible epistatic interactions.

Let a trait be affected by 3 QTLs localised at 3 markers **M1**, **M2** and **M3** respectively. The AnOVA is computed for the linear model:

$$M1 + M2 + M3 + M1 : M2 + M1 : M3 + M2 : M3 + M1 : M2 : M3$$

The R square for each genotypic group is the comparison of the variance due to the between- groups variability (called Mean Square Effect, or MSeffect) with the within- group variability (called Mean Square Error, or Mserror).

The significance of an epistatic interaction is the significance of the group effect of each interaction computed by the AnOVA. If one wants to store the results within a QTL database, it might be useful to compute all genetic determinants by setting `th=1` and then to extract the significant results by SQL queries.

Value

Return an object of class `rsq` which is a simple data frame with columns:

<code>qtl</code>	The name of the genetic determinant. If the genetic determinant is an individual QTL, the name is formatted as "traitName.chrNumber.orderNumber". In the case of epistasis, the genetic determinant name is formatted as the list of individual genetic determinant (QTL) names separated by ":".
<code>rsq</code>	The R square value (set to NA if not significant: $pF < th$).
<code>pF</code>	The significance (set to NA if not significant: $pF < th$).

```

`cim.peak`*Genome scan using previously detected QTLs as covariates*

Description

Use the LOD peaks previously detected in a peak object to define the additive covariates and perform a single genome scan taking cofactors into account.

Usage

```
cim.peak(cross,peak)
```

Arguments

<code>cross</code>	An object of class <code>cross</code> . See 'qtl' package manual for read.cross function details.
<code>peak</code>	An object of class <code>peak</code> . See define.peak function for details.

Details

Performs a composite interval mapping using the [scanone](#) function with additive covariates previously defined in the related peak object. A scan is performed for traits which are affected by at least one QTL. The additive covariates for each trait are defined as the closest flanking marker to each significant LOD peak (defined in the peak feature `peak_cM`). Each trait scan generates a `scanone` object which is concatenated to the other `scanone` objects.

Value

Return an object of class `scanone`.

classify.qtl

Estimate the acting type of expression QTL

Description

Estimate whether an eQTL is cis- or trans- acting.

Usage

```
classify.qtl(cross, peak, etrait.coord, data.gmap)
```

Arguments

cross	An object of class cross. See 'qtl' package manual for read.cross function details.
peak	An object of class peak. See define.peak for details.
etrait.coord	A data.frame with column names "etrait.name", "chr", "start", "stop" specifying the etrait (expression trait) location on the genome: <ol style="list-style-type: none"> etrait.coord\$array_element_name is character strings vector specifying the name of the etraits. etrait.coord\$chr is a vector of integers specifying the chromosome on which the markers are localized. etrait.coord\$start is a vector of integers specifying the start of the etrait's sequence in base pair. etrait.coord\$stop is a vector of integers specifying the stop of the etrait's sequence in base pair.
data.gmap	A data.frame with column names "Marker", "chr" and "PP" specifying the marker's physical location. Those ones must be the same markers defined in the related cross object. <ol style="list-style-type: none"> data.gmap\$Marker is a vector character strings specifying the names of markers. data.gmap\$chr is a vector of integers specifying the chromosomes on which the markers are localized.

3. `data.gmap$PP` is a vector of integers specifying the physical marker locations on the chromosomes in base pair.

Details

Useful in the case of genome-wide expression QTL mapping. Determines cis-acting and trans-acting eQTL (or cis- and trans- eQTL) and gives a basic overview about the global eQTL network. The (potential) cis-eQTL are those which colocalize with the controlled gene. These could be typically explained by a modification within a gene promoter and therefore actually correspond to a cis-regulation (note that it would remain to be confirmed on a case by case basis: due to the lack of precision in QTLs localization for all analysis methods, a cis-acting is still biologically hypothetical; plus it could also correspond to a trans-acting eQTL localised close to its target gene). eQTLs which contains the regulated gene within their LOD support interval are classified in this category as cis. The trans-acting eQTLs are defined as those which do not colocalize with the affected gene. These could typically correspond to the mode of action of a transcription factor on the regulation of another gene's expression. eQTL which do not contain the regulated gene within their LOD support interval are classified as trans.

Value

The input peak object is returned with a component type added to the components of `names(peak\strait\chromosome)` for each previously detected QTL:

type	cis or trans for cis- and trans- eQTL respectively. <NA> if the etrait location is unknown or not nuclear.
------	------------------------------------------------------------------------------------------------------------

Note

The QTL support interval locations are defined within a peak object. This classification (performed by `classify.qtl`) depends entirely on the support interval definition computed by the `define.peak` function. This function tend to underestimate cis-eQTL number as LOD-drop value are more conservative. This, however, does not replace the scientist's own manual examination of the LOD curve.

cleanphe	<i>Remove undesired phenotypes and LOD results from cross and scanone object respectively</i>
----------	-----------------------------------------------------------------------------------------------

Description

Drops the phenotypes or the LOD results within an object of class `cross` or `scanone` respectively. The names of the phenotypes and the lodcolumns to be removed are defined by a character string or regular expression.

Usage

```
cleanphe(x, string = "Buffer")
```

Arguments

<code>x</code>	An object of class <code>cross</code> or class <code>scanone</code> containing at least two phenotypes. See 'qtl' package manual for <code>read.cross</code> and <code>scanone</code> functions details.
<code>string</code>	The string which describes the names of the phenotypes or the results to remove. It can be defined as a regular expression or just the name of a column. See <code>grep</code> for details.

Details

This function is useful to systematically dropping phenotypes like buffers or controls existing in microarray data or clean out the scanone results in context of expression QTL mapping. The names of the phenotypes and results from objects of `cross` and `scanone` class are column names which

are defined by a single string or a regular expression specified by the argument string. The grep function searches the data to be removed as follow:

```
grep(string, names(x)) when x have class scanone.
grep(string, names(x\[extract_itex]pheno)) when x have class cross.
```

Value

Returns the input cross or scanone object.

```

cover.peak

List QTLs within a genetical region from a peak object

Description

List QTLs which cover a given genetical region from peak object data.

Usage

```
cover.peak(peak, pos, chr, pre=0)
```

Arguments

peak	An object of class peak. See define.peak function for details.
pos	A single numeric value : the genetic position.
chr	A single integer value : the chromosome.
pre	A single numeric value : the precision of the targeted genetic position.

Details

This function searches for the QTL from peak object which totally cover a genetical region. The targeted genetic region is defined as a single genetic position pos around which the QTLs are searched; the size of this region is defined by pre which is the max distance from pos on which the QTLs are searched. pre=0 will set to search QTLs which cover only the single genetic position pos. The QTLs are defined by LOD peaks with a support interval in a peak object.

Value

return a data frame of class peak.array

# return the list of QTL which colocalize at 4 cM on chromosome 3
my_peak <- cover.peak(out.peak,pos=4,chr=3,pre=0);
my_peak;

# return the list of QTL which colocalize on the genetic region 4cM-6cM
# on chromosome 4
my_peak <- cover.peak(out.peak,pos=5,chr=4,pre=1);
my_peak;
```

define.peak	<i>Defines the QTL with support interval and exclusionary window</i>
-------------	----------------------------------------------------------------------

Description

Define QTL with LOD drop support interval by using the results of a single QTL genome scan [scanone](#) and using a genetical exclusionary window.

Usage

```
define.peak(scanone, lodcolumn=1, chr, th=2.3, si=1.5, graph=FALSE, window.size=20,
round, save.pict=FALSE, phe.name, ...)
```

Arguments

scanone	An object of class scanone . See qtl package manual for scanone function details.
lodcolumn	Indicates on which of the LOD score columns (phenotypes) the QTLs should be defined. This can be "all" which indicates all LOD score columns. This can also be a vector of integers indicating which of the columns should be used or a strings vector matching the names of the LOD columns, the phenotypes' name, to analyse. See qtl package manual for scanone function details.
chr	An optional vector indicating the chromosomes for which QTLs should be defined.
th	A single numeric value which sets the LOD score significance threshold. Only peaks with LOD score above this value will be analysed.
si	A single numeric value which sets the QTL's Support Interval. si is the value of the accepted drop of LOD score to estimate the likely region on which the QTL is localized.
graph	If TRUE, draws the LOD curve with LOD peaks and support interval for the detected QTLs.
window.size	The exclusionary window size: A single numeric value setting the minimum genetic distance between two distinct QTLs to be considered.
save.pict	If TRUE, save the LOD curves drawn with support interval as png files named like "trait name"_"chromosome"_"a number".png in the current folder.
round	An optional integer indicating the precision to be used for the LOD score. See round function for details.
phe.name	An optional character string specifying the name of the analysed trait. When performing scanone on a single trait, the lodcolumn is named 'lod' and as the analysed trait.
...	Passed to the functions plot and plot.scanone when they are called (if graph=TRUE). Passed the maximum size of the genomic region parameter: m=10 should set 2*10cM for the inferior and the superior SI bounds from the position of the peak

Details

This function is used to detect and report QTL regions from a one-QTL genome scan performed by the `scanone` function. A QTL is considered as a genomic region defined by a maximum LOD score peak value, its position and the position of its support interval (here called `dQuoteSI`). The SI is estimated by the accepted drop of LOD score from the maximum LOD value defining the QTL region (the LOD peak). The FDR falls as the QTL SI size increases with lower LOD scores away from the peak. Usually we use `si=1.5` or `si=2`. A genetic exclusionary window sets the minimum distance between two distinct QTLs which we consider being able to detect and depends directly on the size of the population. Due to the shape of the LOD curve, the drop of LOD score cannot be reached in some cases. Therefore a maximum SI size is set at 20 cM by default. `m=10` will set 2×10 cM for the inferior and the superior SI bounds. `graph=TRUE` specify to draw the LOD curves and the LOD SI on different chart for each QTL on their chromosome. No graphical setup has been defined and therefore they will be drawn one above the other in the same R graphical window. To setup the graph page and print all the charts in same window, one may use the graphical parameter `mfrow` of the R function `par()` according specific needs before launching `define.peak`. You may not want to set `graph=TRUE` and `lodcolumn="all"` at the same time depending on the amount of data. The parameter `save.pict` is useful to save systematically all charts generated by `define.peak`. These graphs are already page setted by the usual graphical functions (like `mfrow`).

Value

Returns an object of class `peak` which is a list of components corresponding to traits. `names(peak)` contains the names of the traits. Each trait is itself a list with elements corresponding to chromosomes. For chromosomes on which no QTL have been detected, `peak\${trait}\$chromosome` contains a NA value (where chromosome is the number identifying the chromosome). For those on which a QTL has been detected `peak\${trait}\$chromosome` contains a data frame where rows are detected QTLs and columns are peak features (which describe QTLs). `names(peak\${trait}\$chromosome)` contains the peak features:

<code>lod</code>	The peak's LOD score.
<code>mname.peak</code>	The maximum LOD peak's (pseudo-)marker name.
<code>peak.cM</code>	The maximum LOD peak's genetic position in centiMorgan (cM).
<code>mname.inf</code>	The (pseudo-)marker's name corresponding to the inferior si bound.
<code>inf.cM</code>	The genetic position of the inferior SI bound in centiMorgan (cM).
<code>mname.sup</code>	The (pseudo-)marker's name corresponding to the superior SI bound.
<code>sup.cM</code>	The genetic position of the superior SI bound in centiMorgan (cM).
<code>si.quality</code>	The subjective quality if the support interval. Due to the shape of the LOD curves and the methods used to define the LOD peaks, the subjective quality of the QTLs are various.

The subjective quality of the support interval

A QTL whose support interval can be reached and defined, has more weight than a QTL whose support interval cannot and has been defined by its maximum size (argument `m`). This quality information corresponds to symbols indicating, how each were defined by the bounds of the QTL support interval. The symbols on the right side gives the information for the superior SI bounds and so on for the left sided bounds. '+' indicates that the LOD-drop support interval has been reached.

'<->' and '<->' indicates that the LOD-drop SI hasn't been reached before the maximum SI size (defined by *m* argument) for the inferior and the superior bounds respectively. '|' indicates that the LOD-drop SI has been delimited by the beginning or the end of the LOD curve either for the inferior or superior bounds respectively. Therefore, the quality symbols '|->' indicates that the SI has been delimited on the left by the beginning of the LOD curve and on the right by the maximum SI size. Therefore, the drop of LOD score is not reached on either the left or right. '+|' indicates that the SI has been reached on the left but has been delimited on the right by the end of the LOD curve.

Symbols - *Signification*

"++" - *The QTL is bounded by a LOD-drop with both both SI sides reached.*

"<-->" - *The QTL is bounded by the *m* parameter. The SI is not reached.*

"+|" - *The QTL is bounded by the end of the chromosome on the right and by a SI on the left.*

"|+" - *The QTL is bounded by the beginning of the chromosome on the left and by a SI on the right.*

"<-|" - *The QTL is bounded by the end of the chromosome on the right and *m*/2 on the left.*

"|->" - *The QTL is bounded by the beginning of the chromosome on the left and *m*/2 on the right.*

drop.peakfeat	<i>Erase peak features in peak object</i>
---------------	-------------------------------------------

Description

Erase chosen peak features informations from a peak object.

Usage

```
drop.peakfeat(peak, feat)
```

Arguments

peak	An object of class peak. See <code>define.peak</code> function for details.
feat	A character string vector containing the names of the features to delete. Features could be: "additive.effect", "peak.bp", "inf.bp", "sup.bp" or "type". See <code>calc.adeft</code> , <code>localize.qtl</code> , <code>classify.qtl</code> functions for details.

Details

In peak object, QTL is defined by peak features. This function is useful to erase some peak features by avoiding to redo all the analyses (mainly the `define.peak` function). Only the peak features generated by the functions `calc.adeft`, `localize.qtl` and `classify.qtl` should be removed. This function is used by the functions 'calc.adeft', 'localize.qtl' and 'classify.qtl'.

Value

An object of class peak

out.peak;
```

eqlversion	<i>Installed version of R/eql</i>
------------	-----------------------------------

Description

Print the version number of the currently intalled version of R/eql

Usage

```
eqlversion()
```

Value

A character string with the version number of the currently installed version of R/eql.

Author(s)

Hamid A Khalili, <hamid.khalili@gmail.com>

See Also

[version](#)

genoplot	<i>Genome plot of the eQTL data on the expression traits locations</i>
----------	------------------------------------------------------------------------

Description

Plots the estimated eQTL positions with the genomic positions of the controlled gene.

Usage

```
genoplot( peak.array, cross, etrait.coord, data.gmap, chr.size, save.pict=FALSE, ...)
```

Arguments

<code>cross</code>	An object of class <code>cross</code> . See 'qtl' package manual for <code>read.cross</code> function details.
<code>peak.array</code>	An object of class <code>peak.array</code> . See <code>peak.2.array</code> function for details.
<code>etrait.coord</code>	A data frame specifying the <code>etrait</code> genomic locations with columns: <code>etrait.name</code> a factor with array element or gene name as levels. <code>chr</code> an integer vector determining the chromosome. <code>start</code> an integer vector determining the GST start location in base pair. <code>stop</code> an integer vector determining the GST stop location in base pair.
<code>data.gmap</code>	A data frame with column names "Marker", "chr" and "PP" specifying the marker physical locations. Those one must be the same markers defined in the related <code>cross</code> object. <code>data.gmap\$Marker</code> is a vector character strings specifying the names of markers. <code>data.gmap\$chr</code> is a vector of integers specifying the chromosome on which the markers are localized. <code>data.gmap\$PP</code> is a vector of integers specifying the physical marker location on the chromosome in base pair.
<code>chr.size</code>	A vector of integer specifying the size of the chromosomes in base pair in order of the chromosomes.
<code>save.pict</code>	If TRUE, save each charts generated by <code>genoplot</code> as png files in the current folder.
<code>...</code>	Ignored at this step.

Details

Useful for genetical genomics studies. This function gives a graphical overview of the global eQTL network by plotting the estimated eQTL positions with the genomic positions of the affected traits. Six charts are generated and all locations data are represented on a physical scale. The genomic ditribution of both affected traits and QTLs are described by two histograms. If `save.pict=TRUE`, these histograms are saved as `./histogram_controlled_gst.png` and `./histogram_qtl.png` files, respectively. The `etrait~eQTL` plot are represented with LOD color scale (from green to red in order of increasing LOD score, blue representing the average LOD SCORE) and with additive effect color scale (from green to red in order of increasing additive effect, yellow representing the null additive effect). Four `etrait~eQTL` plot are generated representing the eQTL locations as single LOD peaks or support interval regions, both with LOD and additive effect color scales. If `save.pict=TRUE`, these plot are saved as `lod_dotplot_traitxqtl.png`, `ae_dotplot_traitxqtl.png`, `lod_splot_traitxqtl.png` and `ae_splot_traitxqtl.png` files.

Value

return a list with elements:

<code>coord_etrait</code>	the <code>etrait</code> coordinates.
<code>coord_qtl</code>	the QTL coordinates.
<code>limit</code>	the chromosomes limits.
<code>add_etrait</code>	the cumulates size of the chromosomes in bp for the <code>etrait</code> .
<code>add_qtl</code>	the cumulates size of of the chromosomes in bp for the QTL.

gpt

*Global Permutation Threshold***Description**

Computes a Global Permutation Threshold to estimate a LOD score significance threshold.

Usage

```
gpt(cross, n_etrait=100, n_perm=1000)
```

Arguments

cross	An object of class cross. See 'qlt' package manual for read.cross function details.
n_etrait	An integer which specifies the number of individuals on which the permutation test are performed.
n_perm	An integer. This argument defines the number of permutation replicates.

Details

Computes the Global Permutation Threshold which fits to a single-QTL scan (using scanone function) by permuting the phenotypes while maintaining the genotype for a sample of individuals randomly chosen within an object of class cross. The GPT estimates the LOD score significance threshold if 1000 permutations at least are computed on 100 individuals at least (i.e. 100,000 permutations).

Value

An object of class scanoneperm

## End(Not run)
```

Description

R/qtl needs to import some data in addition to those necessary for R/qtl package: the physical data of the genetic markers and the physical coordinates of the probes used to measure the expression traits.

The physical data of the genetic map

This is a simple data frame with columns "Marker", "chr" and "PP" as described for BSpgmap dataset. You can import this data any way you prefer to obtain the data frame. Described here is one simple way to import it from a file:

- **The file format:**

The first line contains the headings of the columns separated by coma. The following lines contains the informations needed (coma separated). This file could be created as CSV file from Excel or a simple text editor. Of course, this information describes the map of the experiment stored as cross object (here seed10). The markers must appear in the same order as the markers and chromosomes in the cross object (in the same order of the map !).

Take a look on the sample file:

```
"Marker", "chr", "PP"
"MSAT100008", 1, 8639
"T1G11", 1, 1243250
"F21M12", 1, 3212191
"IND4992", 1, 4992444
"IND6375", 1, 6375557
"MSAT1.10", 1, 7296649
"MSAT108193", 1, 8192951
etc...
```

Take a look within R to the cross object:

```
seed10.clean$geno$'1'$map
seed10.clean$geno$'2'$map
seed10.clean$geno$'3'$map
etc...
```

- **The R command to import the data within R:**

```
a_new_pgmap <- read.table("./fileName", header=TRUE, sep=",");
```

The code should work if it is placed within the R working directory. If not replace `./fileName` with the correct directory (Windows users must use either forward slashes `/"` or double backslashes `"\"`).

The coordinates of the expression traits

This is a simple data frame with columns "etrait.name", "chr", "start" and "stop" as described for ATH.coord. By the same way as the map data importation, you can do by the way you wanted. The importation process is quite similar. Here the file can describe more expression trait than the phenotypes described in cross object. Of course all etraits described in cross object must have coordinates in the file.

- **The file format:**

```
"etrait.name", "chr", "start", "stop"
"CATMA1A00010", 1, 4707, 4972
"CATMA1A00020", 1, 6442, 6653
"CATMA1C71002", 1, 7579, 7791
"CATMA1A00030", 1, 12268, 12486
"CATMA1A00035", 1, 30923, 31142
"CATMA1A00040", 1, 31232, 31381
"CATMA1A00045", 1, 33814, 34211
"CATMA1A00050", 1, 38785, 38971
etc...
```

- **Take a look within R to the cross object:**

```
names(seed10.cleaned$phe)[1:10]
```

- **The R command to import the data within R:**

```
new_probes.coord <- read.table('path_to_file', header= TRUE, sep=",");
```

localize.qtl

Compute QTL physical positions from QTL genetic positions

Description

Computes QTL physical positions from QTL genetic positions from an object of class peak and the marker physical positions.

Usage

```
localize.qtl( cross, peak, data.gmap, round )
```

Arguments

cross	An object of class cross. See 'qtl' package manual for read.cross function details.
peak	An object of class peak. See define.peak for details.
data.gmap	A data.frame with column names "Marker", "chr" and "PP" specifying the marker physical locations. Those one must be the same markers described in the related cross object. data.gmap\$Marker is a vector of character strings specifying the names of the markers. data.gmap\$chr is a vector of integers specifying the chromosomes on which the markers are localized. data.gmap\$PP is a vector of integers specifying the physical marker locations on the chromosomes in base pair.
round	An optional integer indicating the precision to be used for the physical position. The physical position being estimated, non integer nucleotidic position values could be obtained. See round function for details.

Details

Linearly computes the physical position from $\text{peak}\$peak_cM$ and the flanking marker locations:

$$A + B/C * D$$

A is the physical position of the first flanking marker. **B** and **C** are the genetic and the physical distances between the two flanking markers respectively. **D** is the genetic position of the qtl peak.

Value

The input peak object is returned with components added to components of names (peak\$trait\$chromosome) for each previously detected QTL:

peak.bp	is the physical location of the maximum LOD peak.
inf.bp	is the physical location of the SI lower bound.
sup.bp	is the physical location of the SI upper bound.

map.peak

Summaries maximum LOD peak position from peak object

Description

Summaries all maximum LOD peaks position from peak object as a data frame. This function is useful for Composite Interval Mapping to define as co-factor previously detected QTLs.

Usage

```
map.peak(peak)
```

Arguments

peak An object of class peak. See [define.peak](#) function for details.

Details

Summaries all detected QTLs location from peak object as a data frame. This function could be used by the function `wash.covar` and gives an overview of the covariates which can be used for a Composite Interval Mapping.

Value

Returns a data frame with columns:

<code>trait</code>	The names of the affected traits.
<code>chr</code>	The names of the chromosomes on which the QTL has been detected.
<code>cM</code>	The genetic position of the detected QTL.

Author(s)

Hamid A. Khalili

Examples

```
data(seed10);

out.em <- scanone( seed10, pheno.col=1:50, model='normal', method='hk');
out.peak <- define.peak(out.em, 'all');

covar <- map.peak(out.peak);

covar;
```

mnames.map

List all markers from a cross object

Description

Return the list of all markers for all of the chromosomes.

Usage

```
mnames.map(cross)
```

Arguments

<code>cross</code>	An object of class <code>cross</code> . See 'qtl' package manual for <code>read.cross</code> function details.
--------------------	----------------------------------------------------------------------------------------------------------------

Details

Returns the list of all markers of the cross object sort by chromosome appearance and the marker relatives position. This function is used by the `cim.peak` function.

Value

A vector containing all marker names sort by the marker relatives position and chromosomes appearance.

Author(s)

Hamid A. Khalili

Examples

```
data(seed10);  
mnames.map(seed10);
```

peak.2.array

Build a simple array from a peak object

Description

Build a simple array from a peak object.

Usage

```
peak.2.array(peak)
```

Arguments

`peak` An object of class `peak`. See `define.peak` for function details.

Details

Useful for a genome-wide eQTL mapping. Formats the results as a simple array which allows to use all of classical R functions (graphical, statistical, summaries, ...) and permits the results to be manipulated in the simplest way. All expression traits are represented and those which are not affected by any QTL, contain the empty data <NA> in each column.

Value

Return an object of class `array.peak` which is a data frame with columns:

<code>trait</code>	The name of the studied traits.
<code>chr</code>	The number of the chromosome.
<code>mname.peak</code>	The peak (pseudo-)marker name when a QTL was detected. <NA> if no QTL was detected.
<code>lod</code>	The peak LOD score when a QTL was detected. <NA> if no QTL was detected.
<code>peak.cM</code>	The genetic position of the peak in centiMorgan(cM) when QTL was detected. <NA> if no QTL was detected.
<code>mname.inf</code>	The (pseudo-)marker name corresponding to the inferior SI bound when a QTL was detected. <NA> if no QTL was detected.
<code>inf.cM</code>	The genetic position of the inferior SI bound in centiMorgan(cM) when a QTL was detected. <NA> if no QTL was detected.
<code>mname.sup</code>	The (pseudo-)marker names corresponding to the superior SI bound when a QTL was detected. <NA> if no QTL was detected.
<code>sup.cM</code>	The genetic position of the superior SI bound in centiMorgan(cM) if a QTL was detected. <NA> if no QTL was detected.
<code>si.quality</code>	The subjective quality of the support interval. See 'define.peak' for details.

According to the methods used to create the peak object, the following columns could be present:

<code>additive.effect</code>	The additive effects of the QTL. <NA> if no QTL has been detected.
<code>peak.bp</code>	The physical position of the maximum LOD peak. <NA> if no QTL was detected.
<code>inf.bp</code>	The physical position of the SI lower bound. <NA> if no QTL was detected.
<code>sup.bp</code>	The physical position of the SI upper bound. <NA> if no QTL was detected.
<code>type</code>	The estimated type of the eQTLs (trans or cis for cis- and trans- eQTL respectively). <NA> if no QTL was detected or in case of non nuclear expression trait.

Examples

```
data(seed10);

# Defining QTLs for all traits
out.em <- scanone( seed10, pheno.col=1:50, model='normal', method='hk');
out.peak <- define.peak( out.em, 'all', graph=TRUE, save.pict=TRUE);
```

```
## Not run: out.array <- peak.2.array(out.peak);
# Computing additive effect
out.peak <- calc.adeff(seed10,out.em,out.peak);
# Localizing peak
data(BSpomap);
out.peak <- localize.qtl(seed10,out.peak,BSpomap);

## End(Not run)

out.array <- peak.2.array(out.peak);
```

peaksummary	<i>Print summary of QTL definition</i>
-------------	----------------------------------------

Description

Print summary information about QTL contained in a peak object.

Usage

```
peaksummary(peak.array,cross,exc=data.frame(inf=0,sup=0,chr=NA),graph=FALSE,...)
```

Arguments

peak.array	An object of class peak.array. See peak.2.array and Rsq.2.array functions for details.
cross	An object of class cross. See "qtl" package manual for read.cross function details.
exc	A data frame with columns inf, sup and chr which represent a genomic region to exclude from the summary. inf, sup,chr represents the genomic location in base pair (start and stop of the sequence to exclude respectively), chr specify the chromosome. They are single numeric values.
graph	If TRUE, print summary graphs.
...	Ignored at this point.

Value

Returns a list containing a variety of summary information about QTL distribution according to the peak feature.

Note

No page settings have been specified in the peaksummary function therefore if graph=TRUE all graphs will appear one above the other within the same R graphical window. You should specified the use by the parameter mfrow of the R function par() to setup the graph page.

```

data(seed10);

out.em <- scanone( seed10, pheno.col=1:50, model='normal', method='hk');
out.peak <- define.peak(out.em,'all');
out.peak <- calc.adeft(seed10,out.em,out.peak);

data(BSpomap);
out.peak <- localize.qlt(seed10,out.peak,BSpomap);
out.array <- peak.2.array(out.peak);

# Whole QTL summary with graph
par(mfrow=c(2,4));
peaksummary( out.array, seed10, graph=TRUE);
par(mfrow=c(1,1));

# QTL summary with graphs excluding the QTLs localized
# on chromosome 3 between 5000 and 6000 bp.
par(mfrow=c(2,4));
peaksummary( out.array, seed10, exc=data.frame(inf=5000,sup=6000,chr=3), graph=TRUE);
par(mfrow=c(1,1));

```

plotRsq

*Plot R square data***Description**

Draw histograms of R square value distribution for rsq object.

Usage

```
plotRsq( rsq, par=c(2,2), ...)
```

Arguments

rsq	An object of class rsq. See calc.Rsq for function details.
par	A vector of two integers corresponding to the mfrow parameter of the par() function.
...	Passed to the function hist and par when they are called.

Details

Draw histograms of R square value distribution from an object of class `rsq`. Three histograms are drawn: the first one shows the R square value distribution of single QTLs. The second shows the distribution for QTL interactions. The last one shows all R square values distribution.

Value

none

  map.function='kosambi', stepwidth='fixed');

out.em <- scanone( seed10, pheno.col=1:50, model='normal', method='hk');
out.peak <- define.peak(out.em, 'all');
out.rsq <- calc.Rsq(seed10, out.peak);

# plotting R square data
plotRsq(out.rsq);
plotRsq(out.rsq, par=c(1,3));
```

pseudo.map

The makers and pseudo-markers genetic map

Description

Lists the markers and pseudo-markers genetic positions for all of the chromosomes.

Usage

```
pseudo.map( cross )
```

Arguments

`cross` An object of class `cross`. See 'qtl' package manual for `read.cross` function details.

Details

This function lists the markers and pseudo-marker genetic positions for all of the chromosomes. This function is used by others functions. It is necessary to have previously perform the `calc.genoprob` function before using this function.

Value

A vector containing containing the genetic position of markers and pseudo-marker for all of the chromosomes sort by positions and chromosomes appearance.

Note

It is necessary to previously perform the `calc.genoprob` function.

pseudo.map(seed10);
```

Rsq.2.array

Add R square data to peak.array data frame

Description

Adds the single QTL R square data to the related general QTL description contained within `peak.array` data frame.

Usage

```
Rsq.2.array(rsq,peak.array)
```

Arguments

<code>rsq</code>	An object of class <code>rsq</code> . See <code>calc.Rsq</code> for function details.
<code>peak.array</code>	An object of class <code>peak.array</code> . See <code>peak.2.array</code> for function details.

Details

Useful to store whole single QTL description within a simple array by adding the single QTL R square data. Add two columns containing the R square data from rsq object to the related peak.array data frame. Column Rsq contains the R square values and column RpF contains the R square significance. The R square data is computed by the function calc.Rsq.

Value

Returns an object of class rsq which is a simple data frame with columns:

qtl	The name of the genetic determinant. If the genetic determinant is an individual QTL, the name is formatted as 'trait_name'. 'chr_number'. 'a_number'. In the case of interactives QTL, the genetic determinant name is formatted as the list of individual genetic determinant names separated by ': '.
rsq	The Fisher value (set to NA if not significant: $pF < th$).
pF	The significance (set to NA if not significant: $pF < th$).

```

`seed10`*Data on gene expression level variation*

Description

Sample data from an experiment on the expression level variation in the *A.thaliana* seed at 10 day after pollination.

Usage

```
data(seed10)
```

Format

An object of class `cross` and `riself`.

Details

There are 420 RIL individuals typed at 69 markers and 160 individuals have been retained for phenotyping. The population is the 33RV Versailles RIL population Bay x Sha. See references below. The phenotype is a sample of 500 anonymized Gene Sequence Tags hybridization signals measured on the CATMA microarray. Some probes are not GST. You need to remove them with the `cleanphe` function with the parameter `string="CHLORO"` and `string="MITO"`. See references below.

```

`wash.covar`*Erase additive covariates LOD peaks on the LOD curve*

Description

Sets LOD curve to 0 for a given region size around cofactors included in CIM.

Usage

```
wash.covar(scanone, covar, window.size=20)
```

Arguments

- | | |
|--------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>scanone</code> | An object of class <code>scanone</code> . See 'qtl' package manual for <code>scanone</code> function details. |
| <code>covar</code> | A data frame with columns 'trait', 'chr' and 'cM'.
<code>covar\$trait</code> is a character strings vector which specifies the names of the traits.
<code>covar\$chr</code> is an integer vector which specifies the number of the chromosome.
<code>covar\$cM</code> is a numeric vector which specifies the cofactor position in cM. |
| <code>window.size</code> | a single numeric value which specifies the size of the region to set at zero LOD. |

Details

This function is useful to extract the new QTLs from composite interval mapping results. The artifactual LOD peak value obtained from the cofactors are set at zero LOD. Then the QTLs are defined by using the function `define.peak`. The cofactors loci are defined in a data frame which can be performed by the function `map.peak`. In this case, the cofactors will be at the maximum LOD peak location defined within the related peak object.

Value

The input `scanone` object is returned.
