Package 'tidyposterior'

June 11, 2020

Version 0.0.3

Title Bayesian Analysis to Compare Models using Resampling Statistics

Description Bayesian analysis used here to answer the question: ``when looking at resampling results, are the differences between models 'real'?'' To an-

swer this, a model can be created were the performance statistic is the resampling statistics (e.g. accuracy or RMSE). These values are explained by the model types. In doing this, we can get parameter estimates for each model's affect on performance and make statistical (and practical) comparisons between models. The methods in-

cluded here are similar to Benavoli et al (2017) $ihttp://jmlr.org/papers/v18/16-305.html_i$.

contrast_models

Estimate the Difference Between Models

Description

The posterior distributions created by $perf_mod()$ can be used to obtain the posterior distribution of the difference(s) between models. One or more comparisons can be computed at the same time.

Usage

contrast_models(x, list_1 = NULL, list_2 = NULL, seed = sample.int(10000, 1))

Arguments

х	An object produced by perf_mod().
list_1, list_2	Character vectors of equal length that specify the specific pairwise con- trasts. The contrast is parameterized as list_1[i] -list_2[i]. If the defaults are left to NULL, all combinations are evaluated.
seed	A single integer for sampling from the posterior.

Details

If a transformation was used when ${\sf x}$ was created, the inverse is applied *before* the difference is computed.

Value

A data frame of the posterior distribution(s) of the difference(s). The object has an extra class of "posterior_diff".

ggplot.posterior Visualize the Posterior Distributions of Model Statistics

Description

A simple violin plot is created by the function.

Usage

```
## S3 method for class 'posterior'
ggplot(data, mapping = NULL, ..., environment = NULL, reorder = TRUE)
```

Arguments

data	An object produced by tidy.perf_mod().
mapping,, e	nvironment
	Not currently used.
reorder	A logical; should the ${\tt model}$ column be reordered by the average of the
	posterior distribution?

Details

Deprecated

Value

A ggplot2::ggplot() object using ggplot2::geom_violin() for the posteriors.

Examples

```
data(ex_objects)
library(ggplot2)
ggplot(posterior_samples)
```

ggplot.posterior_diff Visualize the Posterior Distributions of Model Differences

Description

A density is created for each contrast in a faceted grid.

Usage

```
## S3 method for class 'posterior_diff'
ggplot(data, mapping = NULL, ..., environment = NULL, size = 0)
```

Arguments

data	An object produced by contrast_models().
mapping,, e	nvironment
	Not currently used.
size	The size of an effective difference. For example, a $5\backslash$ "real" difference.

Details

Deprecated

Value

A ggplot2::ggplot() object using geom_density faceted by the models being contrasted (when there are 2 or more contrasts).

Examples

```
data(ex_objects)
library(ggplot2)
ggplot(contrast_samples)
```

no_trans

Simple Transformation Functions

Description

A set of objects are contained here to easily facilitate the use of outcome transformations for modeling. For example, if there is a large amount of variability in the resampling results for the Kappa statistics, which lies between -1 and 1, assuming normality may produce posterior estimates outside of the natural bound. One way to solve this is to use a link function or assume a prior that is appropriately bounded. Another approach is to transform the outcome values prior to modeling using a Gaussian prior and reverse-transforming the posterior estimates prior to visualization and summarization. These object can help facilitate this last approach.

Usage

no_trans

logit_trans

Fisher_trans

ln_trans

inv_trans

Format

An object of class list of length 2.

perf_mod

Details

The logit_trans object is useful for model performance statistics bounds in zero and one, such as accuracy or the area under the ROC curve.

ln_trans and inv_trans can be useful when the statistics are right-skewed and strictly positive.

Fisher_trans was originally used for correlation statistics but can be used here for an metrics falling between -1 and 1, such as Kappa.

Examples

logit_trans\$func(.5)
logit_trans\$inv(0)

perf_mod

Bayesian Analysis of Resampling Statistics

Description

Bayesian analysis used here to answer the question: "when looking at resampling results, are the differences between models 'real?" To answer this, a model can be created were the *outcome* is the resampling statistics (e.g. accuracy or RMSE). These values are explained by the model types. In doing this, we can get parameter estimates for each model's affect on performance and make statistical (and practical) comparisons between models.

Usage

```
perf_mod(object, ...)
## S3 method for class 'rset'
perf_mod(object, transform = no_trans, hetero_var = FALSE, formula = NULL, ...)
## S3 method for class 'vfold_cv'
perf_mod(object, transform = no_trans, hetero_var = FALSE, ...)
## S3 method for class 'resamples'
perf_mod(
    object,
    transform = no_trans,
    hetero_var = FALSE,
    metric = object$metrics[1],
    ...
)
## S3 method for class 'data.frame'
perf_mod(object, transform = no_trans, hetero_var = FALSE, formula = NULL, ...)
```

Arguments

object	A data frame or an rset object (such as rsample::vfold_cv()) containing the id column(s) and at least two numeric columns of model performance statistics (e.g. accuracy). Additionally, an object from caret::resamples can be used.
	Additional arguments to pass to <code>rstanarm::stan_glmer()</code> such as <code>verbose</code> , prior, seed, family, etc.
transform	An named list of transformation and inverse transformation functions. See logit_trans() as an example.
hetero_var	A logical; if TRUE, then different variances are estimated for each model group. Otherwise, the same variance is used for each group. Estimating heterogeneous variances may slow or prevent convergence.
formula	An optional model formula to use for the Bayesian hierarchical model (see Details below).
metric	A single character value for the statistic from the resamples object that should be analyzed.

Details

These functions can be used to process and analyze matched resampling statistics from different models using a Bayesian generalized linear model with effects for the model and the resamples.

By default, a generalized linear model with Gaussian error and an identity link is fit to the data and has terms for the predictive model grouping variable. In this way, the performance metrics can be compared between models.

Additionally, random effect terms are also used. For most resampling methods (except repeated V-fold cross-validation), a simple random intercept model its used with an exchangeable (i.e. compound-symmetric) variance structure. In the case of repeated cross-validation, two random intercept terms are used; one for the repeat and another for the fold within repeat. These also have exchangeable correlation structures.

The above model specification assumes that the variance in the performance metrics is the same across models. However, this is unlikely to be true in some cases. For example, for simple binomial accuracy, it well know that the variance is highest when the accuracy is near 50 percent. When the argument hetero_var = TRUE, the variance structure uses random intercepts for each model term. This may produce more realistic posterior distributions but may take more time to converge.

Examples of the default formulas are:

```
# One ID field and common variance:
   statistic ~ model + (model | id)
# One ID field and heterogeneous variance:
   statistic ~ model + (model + 0 | id)
# Repeated CV (id = repeat, id2 = fold within repeat)
# with a common variance:
   statistic ~ model + (model | id2/id)
# Repeated CV (id = repeat, id2 = fold within repeat)
```

precise_example

```
# with a heterogeneous variance:
   statistic ~ model + (model + 0| id2/id)
# Default for unknown resampling method and
# multiple ID fields:
   statistic ~ model + (model | idN/../id)
```

Custom formulas should use statistic as the outcome variable and model as the factor variable with the model names.

Also, as shown in the package vignettes, the Gaussian assumption make be unrealistic. In this case, there are at least two approaches that can be used. First, the outcome statistics can be transformed prior to fitting the model. For example, for accuracy, the logit transformation can be used to convert the outcome values to be on the real line and a model is fit to these data. Once the posterior distributions are computed, the inverse transformation can be used to put them back into the original units. The transform argument can be used to do this.

The second approach would be to use a different error distribution from the exponential family. For RMSE values, the Gamma distribution may produce better results at the expense of model computational complexity. This can be achieved by passing the family argument to perf_mod as one might with the glm function.

Value

An object of class perf_mod.

precise_example Example Data Sets

Description

Example Data Sets

Details

Several data sets are contained in the package as examples. Each *simulates* an **rset** object but the **splits** columns are not included to save space.

- precise_example contains the results of the classification analysis of a real data set using 10-fold CV. The holdout data sets contained thousands of examples and have precise performance estimates. Three models were fit to the original data and several performance metrics are included.
- noisy_example was also generated from a regression data simulation. The original data set was small (50 samples) and 10-repeated of 10-fold CV were used with four models. There is an excessive of variability in the results (probably more than the resample-to-resample variability). The RMSE distributions show fairly right-skewed distributions.
- concrete_example contains the results of the regression case study from the book *Applied Predictive Modeling*. The original data set contained 745 samples in the training set. 10-repeats of 10-fold CV was also used and 13 models were fit to the data.

- ts_example is from a data set where rolling-origin forecast resampling was used. Each assessment set is the summary of 14 observations (i.e. 2 weeks). The analysis set consisted of a base of about 5,500 samples plus the previous assessment sets. Four regression models were applied to these data.
- ex_object objects were generated from the two_class_dat data in the modeldata package. Basic 10-fold cross validation was used to evaluate the models. The posterior_samples object is samples of the posterior distribution of the model ROC values while contrast_samples are posterior probabilities form the differences in ROC values.

Value

Tibbles with the additional class rset

Examples

```
data(precise_example)
precise_example
```

summary.posterior Summarize the Posterior Distributions of Model Statistics

Description

Numerical summaries are created for each model including the posterior mean and upper and lower credible intervals (aka uncertainty intervals).

Usage

```
## S3 method for class 'posterior'
summary(object, prob = 0.9, seed = sample.int(10000, 1), ...)
```

Arguments

object	An object produced by tidy.perf_mod().
prob	A number p (0 ; p ; 1) indicating the desired probability mass to include in the intervals.
seed	A single integer for sampling from the posterior.
	Not currently used

Value

A data frame with summary statistics and a row for each model.

Examples

data("ex_objects")

summary(posterior_samples)

summary.posterior_diff

Summarize Posterior Distributions of Model Differences

Description

Credible intervals are created for the differences. Also, region of practical equivalence (ROPE) statistics are computed when the effective size of a difference is given.

Usage

```
## S3 method for class 'posterior_diff'
summary(object, prob = 0.9, size = 0, ...)
```

Arguments

object	An object produced by contrast_models().
prob	A number p $(0 \ ; p \ ; 1)$ indicating the desired probability mass to include in the intervals.
size	The size of an effective difference. For example, a $5\backslash$ "real" difference.
	Not currently used

Details

The ROPE estimates included in the results are the columns pract_neg, pract_equiv, and pract_pos. pract_neg integrates the portion of the posterior below -size (and pract_pos is the upper integral starting at size). The interpretation depends on whether the metric being analyzed is better when larger or smaller. pract_equiv integrates between [-size, size]. If this is close to one, the two models are unlikely to be practically different relative to size.

Value

A data frame with interval and ROPE statistics for each comparison.

Examples

```
data("ex_objects")
summary(contrast_samples)
summary(contrast_samples, size = 0.025)
```

tidy.perf_mod

Description

tidy can be used on an object produced by perf_mod() to create a data frame with a column for the model name and the posterior predictive distribution values.

Usage

```
## S3 method for class 'perf_mod'
tidy(x, seed = sample.int(10000, 1), ...)
```

Arguments

Х	An object from perf_mod()
seed	A single integer for sampling from the posterior.
	Not currently used

Details

Note that this posterior only reflects the variability of the groups (i.e. the fixed effects). This helps answer the question of which model is best *for this data set*. If does not answer the question of which model would be best on a new resample of the data (which would have greater variability).

Value

A data frame with the additional class "posterior"
